ABSTRACT

Background: Female breast cancer is one of the causes of the highest cancer mortality and morbidity in the world. It is already known that there is a strong association between smoking and breast cancer. However, the association between smoking and tumor severity is not very clear. The objective of this study was to assess the severity of the breast tumor, using the tumor’s molecular classification as a tool according to its immunohistochemical profile in smoking and non-smoking women.

Methods: This is a longitudinal study in which 208 women with a diagnosis of breast cancer were followed for 17 months, 80 of whom were smokers, and all underwent anatomopathological diagnosis by core biopsy and subsequent immunohistochemistry, followed by treatment indicated according to the type and the clinical staging of the tumor. The severity of the tumor was assessed by its molecular classification according to its immunohistochemical profile.

Results: Smoking was associated with higher mortality. The tumor with the most severe immunohistochemical profile was found in younger smokers. Overall, 19.7% of smokers and 10% of non-smokers had a triple negative tumor. The age of female smokers with triple negative was 48.2 years, and of non-smoking women was 52.6 years (P = 0.005). In 17 months of follow-up, mortality among smokers was 39.5% and for nonsmokers, 20%. Survival was statistically significantly lower among the group of smokers (P=0.01).

Conclusion: Smoking is associated with greater breast cancer severity, as the risk for cancer severity was 5.5 times higher for the smoking group, and survival was statistically significantly lower among the group of smokers.

INTRODUCTION

Breast cancer is one of the causes of the highest cancer mortality and morbidity in the world. It is more prevalent in women, being the major cause of cancer death among them. The profile of women's lifestyle has changed in recent years amid the social transformation occurring in these decades, as well as...
prevalence of diseases that affect women. In this context, the new lifestyle adopted by today’s women, including smoking, explains part of the emergence of certain diseases.\textsuperscript{2,3} For Brazil, according to the National Cancer Institute\textsuperscript{1}, which is the national reference government agency for the treatment of this disease, 59,700 new cases of breast cancer are expected, with an estimated risk of 5.6, 33 cases per 100,000 women.

Breast cancer is a chronic disease characterized by disordered cell growth, resulting from genetic mutations. It is estimated that 90-95\% of them are sporadic (unfamiliar) and result from somatic mutations, damage to genetic material that accumulates throughout life. It is also estimated that 5-10\% are hereditary (family members) due to the inheritance of a germline mutation at birth, which gives these women a greater susceptibility to breast cancer during their lifetime.\textsuperscript{4,5} The modern western model of life produces and reproduces risk factors that directly influence carcinogenesis.\textsuperscript{6}

Some studies have shown that the carcinogenic agents present in tobacco, for example, are polycyclic aromatic hydrocarbons, aromatic amines and N-nitrosamines.\textsuperscript{3,5,7} They can be transported through the bloodstream to the mammary glandular tissue, initiating the neoplastic process by damaging the nuclear DNA content by these agents.\textsuperscript{8} However, it is not entirely clear whether these lesions in the cell DNA caused by these agents make the tumor more aggressive.

A study published in the scientific journal Cancer, from the American Cancer Society, reported the link between tobacco consumption and the most common type of breast cancer in young women. In the study, researchers concluded that patients under 44 years of age who smoke at least one pack of cigarettes a day for at least ten years have a 60\% higher risk of developing tumors. but it is not yet known whether tobacco is related to the severity of the disease.\textsuperscript{9}

Given this, the objective of this study is to compare the severity of breast cancer, according to the molecular classification.\textsuperscript{3,4} According to its immunohistochemical profile (luminal A, luminal B, hybrid luminal, HER 2 overexpression and triple negative)\textsuperscript{5,6}, clinical staging (early encompassing stages from 0 to IIB, and late encompassing stages from III to IV) and survival, among a group of smoking and non-smoking women.

**METHODS**

This is a longitudinal, study with a quantitative approach, involving 208 women with breast carcinoma undergoing treatment at the mastology service of two public hospitals in the State of São Paulo. Among them, 80 were smokers and 128 non-smokers. These were all breast cancer patients treated during the study period. Smokers were considered who regularly used at least one cigarette per day.

Follow-up was carried out by visits every 15 days during the chemotherapy period, and every 30 days after this period. After 17 months, data from these consultations were not included in this study.

This study included women aged 25 to 65 years who at the time of breast cancer diagnosis, had a history of full term pregnancy (38 to 41 weeks of gestational age) with breastfeeding exercise of at least one month.

The study did not include women with other types of previous cancer, men with breast cancer or any other condition of autoimmune diseases or immune deficiency (Figure 1).

![Figure 1. Patient randomization flowchart](image-url)
The diagnosis of breast cancer was made by means of pathological and immunohistochemical exams.\textsuperscript{10,11} Smokers were those who smoked at least one cigarette per day.

The sample was of a convenience nature, from patients who sought the SUS / Unified Health System service, scheduled at random by the “State Regulation System” / SISREG, for the specialty of mastology. The concomitance of the diagnosis of breast cancer and the pregnant puerperal period was considered positive if the diagnosis of breast cancer occurred during pregnancy or in a year after delivery. This protocol was approved by the institutional ethics committee under number 1,064,564. All patients signed a free and informed consent form.

The molecular classification\textsuperscript{3,4} of the tumor followed pre-established criteria that define distinct subtypes according to the molecular studies of breast carcinoma based on the identification of the gene expression profile using the microarray cDNA\textsuperscript{12}: Luminal A, Luminal B, Luminal Hybrid, HER 2 overexpression and triple negative. The clinical staging of the tumors followed the criteria defined by the TNM14 system of the International Union against Cancer (UICC).

The immunohistochemical diagnosis was performed by histological sections, with the respective positive and negative controls undergoing immunohistochemical examination in an automated system with antigen recovery in PTLink (Dako R) and incubation, development and counter staining in AutoStainer Link, using highly sensitive polymer and ready-to-use FLEX antibodies. The calculation of mortality was established from the moment of diagnosis until 17 months after\textsuperscript{12,13}

The statistical analysis was based on the Kolmogorov-Smirnov normality test to assess the distribution of data in relation to normality. Data were presented as means and standard deviations; the odds ratio test was used for categorical variables of severe or non-severe cancer (smoker vs non-smoker) between the groups. The variables related to the results of exams were evaluated by means of analysis of variance. Survival between smokers and non-smokers was analyzed using the Kaplan Meier test. Also, $P < 0.05$ was considered as statistically significant.

**RESULTS**

Of 208 women with breast cancer undergoing treatment, 30 were excluded. Overall, 80 women reported smoking and 128 were classified as non-smokers. No difference was found between the smoking and non-smoking groups in the anthropometric data and age at diagnosis; however in the non-smoking group, there was a higher proportion of women with arterial hypertension, as shown in Table 1.

In general, the molecular profile / gene expression of cancer most frequently found was Luminal B, followed by Luminal A, triple negative, Luminal Hybrid and Her 2 overexpression. However, it was seen that for the group of non-smoking women, there was a higher proportion of women with Luminal A and B types, while among smokers there was a higher proportion of women with Luminal tumor, B and A and negative triple, according to Table 2.

For the sample studied, the clinical stage most frequently found was I, followed by IIB, IIA and IIIA on the same frequency, IIIB and IV. No difference
was found for the groups in relation to clinical staging, as shown in Table 3.

Figure 3 presents the results of the comparative analysis of the risk for the severity of cancer (neoadjuvant chemotherapy groups) for the smoking and non-smoking groups. The analysis showed that the risk for more severe cancer is 5.5 times higher for smokers compared to the group of nonsmoking patients.

Figure 4 shows the results of the assessment of survival among patients with breast cancer, smokers and non-smokers, during a 17-month follow-up period. It was seen that the survival of the non-smoking group was significantly higher than that of the smoking group (P = 0.01). On average, the survival of non-smoking patients was 240 days. It was also found that the risk of death for these patients was 2.2 CI 95% (1.19 - 4.58).
Among the most important results demonstrated are the association between smoking and the histological severity of cancer, and that smoking anticipates the appearance of breast cancer in at least 3 years.

It has been seen that younger patients and smokers have histologically more severe breast cancer. Young patients, under the age of 35, have a higher incidence of high histological grade tumors (undifferentiated cells), high cell proliferation with a high mitotic index, marked cell pleomorphism, high cytoplasm nucleus ratio and higher proportions of tumors with negative estrogen receptors and/or overexpression of HER.

The 2013 platinum study showed that there are approximately 14% of adult smokers in Brazil. The profile of women with breast cancer studied showed a high number of cases associated with tobacco use between the two groups.

In this study, the prevalence of the most serious type of cancer, i.e., triple negative, was almost double in smokers compared to non-smokers, and was also associated with younger women. In a case-control study, it was found that younger age at smoking initiation is related to younger age at diagnosis. Smokers were diagnosed on average ten years earlier than non-smokers, and the incidence of the invasive carcinoma subtype increased with the intensity and duration of smoking. Di Cello et al. suggested that cigarette smoke promotes epithelial-to-mesenchymal transition, producing a more aggressive breast cancer phenotype in vitro.

In a study of 73,388 women, of whom 3721 patients had invasive breast cancer identified during an average follow-up of 13.8 years, the incidence was higher among current smokers and ex-smokers (HR = 1.13) than those who never smoked. It was also seen that women who started smoking before menarche (HR = 1.61) or before the first pregnancy (HR = 1.45) were at higher risk. In this study, mortality was higher among female smokers. This was possibly due to the molecular changes caused by smoking, which enables the development of more invasive tumors with a greater probability of manifestation in other organs. The risk of progression and death from oropharyngeal cancer increases directly as a result of exposure to tobacco at the time of diagnosis and during therapy and is independent of tumor status and treatment.

Tobacco is one of the risk factors for the development of cancer of the respiratory and non-respiratory pathways through carcinogens in its composition, such as polycyclic aromatic hydrocarbons, aromatic amines and N-nitrosamines. Tobacco carcinogens cross the alveolar membrane and go into the bloodstream, where they are transported to the breast tissue via plasma lipoproteins. These carcinogenic agents can be stored in the fatty tissue of the mammary gland and metabolized and activated by the epithelial cells of the breast.

According to the prospective Women’s Health Initiative Observational study, conducted by the Health Partners Research Foundation, Minneapolis / USA, from 1993 to 1998 to determine links between smokers and breast cancer, where 80,000 women were analyzed and followed for ten years, 3250 cases of invasive breast cancer were identified. The results showed that women who smoke before menopause are 16% more likely to develop breast cancer than women who have never smoked in their lives, and ex-smokers have a 9% chance. There is a greater danger among those who smoke after 50 years of age, or those who start smoking in adolescence, periods considered to be a “risk window” for breast cancer. The risk of developing cancer persists until twenty years after the woman stops smoking.

Therefore, the relationship between histologically more severe breast cancer with younger patients and smoking has distinct biological characteristics for worse prognosis and shorter survival. Very consistent data, such as the California Teachers Study, where more than 116,000 women were followed for five years, confirm the importance of smoking in the risk.
of breast cancer, stressing that women with no family history of the disease have a higher risk of cancer when they are smokers. Other studies show that smoking is an independent risk factor for severe skin reactions due to adjuvant radiotherapy for breast cancer.7

**Limitations**

The limitations of this study include the fact that the follow-up was not carried out until five years, where it could better show the outcome of all women. However, this study has important clinical implications. The main implication is that makes this study unique is the fact that smoking is related to the severity of the disease. This information is important in terms of health promotion in encouraging women to avoid smoking, and also to relate the prevalence based on the numbers of women who smoke.

**CONCLUSION**

This study showed an association between smoking and breast cancer with a more severe molecular profile for women who smoke, and a strong relationship was also seen between early smoking initiation and higher mortality. The molecular subtype with triple negative gene expression had a frequency of 19.7% in women who smoked and only 10% in women who did not smoke. The mean age of triple-negative smoking women was 48.2 years and the age of non-smoking women was 52.6 (P= 0.005). In 17 months of follow-up, mortality among smokers and among non-smokers was 39.5% and 20%, respectively.

**ETHICAL CONSIDERATIONS**

This protocol was approved by the institutional ethics committee under number 1,064,564. All patients signed a free and informed consent form.
